Abstract

Background

Early repolarization (ER) has been linked to the risk of sudden cardiac death (SCD) in the general population, although controversy remains regarding risks across various subgroups.

Objective

We investigated whether age and sex influence the prognostic significance of ER.

Methods

We evaluated the 12-lead electrocardiograms of 6631 Finnish general population subjects aged ≥30 years (mean age 50.1 ± 13.9 years, 44.5% men) for the presence of ER (J-point elevation ≥0.1 mV in ≥2 inferior/lateral leads), following them for 24.4 ± 10.3 years. We analyzed the association between ER and the risk of SCD, cardiac death, and all-cause mortality in subgroups according to age (<50 or ≥50 years) and sex.

Results

ER was present in 367 of the 3305 subjects under 50 and in 426 of 3326 subjects aged ≥50 years. ER was not associated with any of the endpoints in the entire study population. After adjusting for clinical factors, ER was associated with SCD (hazard ratio [HR] 1.88; 95% confidence interval [CI] 1.16–3.07) in subjects under 50, but not in older subjects (interaction between ER and age group, *P* = .048). Among the younger subgroup, women with ER had a high risk of SCD (HR 4.11; 95% CI 1.41–12.03), whereas among men ER was not associated with SCD. Finally, ER was not associated with cardiac mortality or all-cause mortality in either age group.

Conclusion

ER associates with SCD in subjects younger than 50 years, particularly in women, but not in subjects 50 years and older.

Keywords

Electrocardiography; Sudden cardiac death; Early repolarization; Epidemiology; Age groups

Introduction

An early repolarization (ER) pattern was previously considered a benign electrocardiogram (ECG) pattern, until it was shown to be associated with idiopathic ventricular fibrillation in three separate case-control studies in 2008.[1–3] Subsequently, researchers found that ER was also associated with all-cause mortality, cardiac death, and sudden cardiac death (SCD) in the general population.[4–8] However, some studies found no link between ER and adverse events.[7] Consequently, researchers attempted to distinguish benign ER patterns from patterns that associate with more unfavorable prognoses.[5,9–12] Furthermore, other studies examined whether the prognosis associated with ER varies across different patient subgroups.[6,9,11] In some studies ER was associated with cardiac mortality, particularly among younger middle-aged subjects, whereas in studies among older subjects ER was not associated with an excess risk.[6,13] In young adult populations, however, ER is a prevalent finding and considered a benign phenomenon.[14–16] Whether age affects the risk of SCD associated with ER in adult subjects remains unclear.

Here, we present our investigation of the association between ER and SCD, cardiac mortality, and all-cause mortality in a Finnish general population cohort and examine whether this association differs between subjects younger than 50 years old and those ≥50 years. Furthermore, we assess whether sex impacted the risk associated with ER in these age groups.

Methods

Study population

The study population consisted of participants of the Mini-Finland Health Survey, a representative sample of the Finnish population, conducted in 1978–1980. The survey consisted of health interviews regarding the subjects' health status, diseases, medications, symptoms, and lifestyle, together with health examinations that measured blood pressure, body mass index, and serum cholesterol, and included an electrocardiogram (ECG). In total, 8000 subjects aged ≥30 years were invited to take part, among whom 7217 participated in the health examination. The extensive survey methods are reported elsewhere.[17] In total, 17 survey participants in this study also participated in a previous cohort study by Tikkanen et al.[4]

Electrocardiographic measurement and analyses

A standard 12-lead ECG was recorded with a paper speed of 50 mm/s for all study subjects during the health examinations conducted in 1978–1980, and subsequently stored for later assessment. The presence of an ER pattern was assessed manually from the original paper ECGs by three physicians in 2016–2018, with assistance from a cardiologist when needed.

An ER pattern was defined and assessed based on a slightly modified version of the recommendations from a published consensus paper.[18] Briefly, we defined an ER pattern as an end-QRS notch or slur on the downward slope of the prominent R-wave at the J-point, with an amplitude of ≥0.1 mV measured with respect to the true baseline determined as the T–P segment. The presence of a pathological Q-wave in the lead with an end-QRS notch or slur was considered a possible peri-infarction block and not classified as an ER pattern.[19] A subject's ECG was considered positive for ER if an ER pattern was present in either ≥2 of the inferior (II, III, or aVF) or ≥2 of the lateral (I, aVL, V4, V5, or V6) leads. An ER amplitude was classified as ≥0.1 mV, but

<0.2 mV or ≥0.2 mV. Each ECG positive for ER was classified according to the configuration of the ER patterns as a slur, notch, or undetermined (no predominant form). The ST-segment was regarded horizontal or descending if the amplitude of the ST-segment 100 ms after the J-point was less than or equal to the amplitude at the J-point end, and ascending if the amplitude was greater than the amplitude at the J-point end.[18] An ECG was classified as a low amplitude T-wave if any T-wave in leads I, II, or V4–V6 was inverted, biphasic, or had an amplitude ≤0.1 mV and ≤10% of the R-wave amplitude in the same lead.[12]

We excluded subjects (n = 248) with missing or unreadable ECGs and subjects (n = 331) with II/III-degree atrioventricular block, ventricular pre-excitation, complete or incomplete bundle branch block, left anterior or posterior fascicular block, QRS duration >110 ms, a pacemaker rhythm, or rare ECG findings not representing the general population. We also excluded subjects (n = 7) with missing data.

Follow-up

Subjects were followed from the baseline examinations in 1978–1980 until the end of 2011 using the Causes of Death Register maintained by Statistics Finland. SCDs likely caused by terminal arrhythmias were determined by two cardiologists. These cardiologists reviewed the data for all deaths from cardiovascular causes from death, hospital, and autopsy records using the SCD definitions based on the modified Cardiac Arrhythmia Suppression Trial (CAST) criteria.[20] In cases of disagreement, a third cardiologist reviewed and classified the case. The primary endpoint was SCD, and the secondary endpoints were cardiac death and death from any cause.

The Mini-Finland Health Survey preceded the current legislation on ethics in medical research. All participants were fully informed about the survey and its implications, participated in the study voluntarily, and were advised that their information would be used for medical research. Agreeing to participate in the baseline health examination was taken to indicate their informed

consent. Record linkage with national health registers to the survey data was approved by the register authorities.

Statistical analysis

Continuous data are presented as the mean ± standard deviation, while categorical data appear as the number of cases and prevalence in the study population in parentheses. We used the general linear model to compare the age- and sex-adjusted mean values for continuous variables, and the prevalence of categorical variables in cross-sectional baseline data. Hazard ratios (HRs), 95% confidence intervals (95% CIs), and *P* values were calculated using the Cox proportional hazards model. We tested the assumption for proportional hazards for each covariate in the final Cox regression model. Age, sex, systolic blood pressure, total serum cholesterol, smoking, diabetes, and coronary artery disease (CAD) were used as covariates in the multivariate models. The statistical significance of the effect modification by age group (subjects aged <50 years and ≥50 years, respectively) and sex were tested using the Wald test by entering an interaction term for ER and age group, and ER and sex, respectively. We considered $P < .05$ as statistically significant. All statistical analyses were performed using IBM SPSS Statistics (version 24) and R (version 3.6.1, https://www.r-project.org/).

Results

Baseline characteristics of subjects

Table 1 summarizes the baseline characteristics. ER was slightly more prevalent among subjects aged ≥50 years compared to subjects under 50 years (12.8% vs 11.1%; *P* = .033). Subjects with ER were more likely male than subjects without ER among subjects aged <50 (68.1% vs 45.7%; *P* < .001). Yet, we found no significant sex difference in subjects ≥50 years. Subjects under 50 with ER had a lower systolic blood pressure, a lower heart rate, and a shorter QRS duration and QTc interval compared to subjects without ER after adjusting for age and sex. Subjects ≥50 years with ER had a lower heart rate and were less likely to have diabetes, but were more likely to take beta blocker medication compared to subjects without ER after adjusting for age and sex.

Impact of age and sex on ER prognosis

Among 3305 subjects under 50, 748 (22.6%) died during a mean follow-up of 30.2 ± 6.4 years, among whom 237 died from cardiac causes (31.7% of all deaths), and 95 from SCD (12.7% of all deaths). Among those ≥50 years old, 2819 of 3326 subjects (84.8%) died during a mean follow-up of 18.7 ± 10.2 years. Among those who died, 1283 deaths resulted from cardiac causes (45.5% of all deaths) and 251 from SCD (8.9% of all deaths).

Across the entire study population, ER was not associated with any of the endpoints (see Supplemental Material). Furthermore, from the different ER patterns, only ER with a low amplitude T-wave (n=158 [19.9% of ER subjects], multivariate-adjusted HR 1.75; 95% CI 1.06–2.87; *P* = .027) was associated with SCD in the entire study population when compared to subjects without ER (see Supplemental Material). Table 2 shows the risk for SCD and the secondary endpoints associated with ER in the age subgroups, and the interaction between ER and age group. ER was not associated with cardiac death or all-cause mortality in either age group. During the

follow-up period, 5.7% of subjects with ER and 2.5% of subjects without ER under 50 suffered an SCD, compared to 7.7% with and 7.5% without ER, respectively, ≥50 years old. We detected a significant interaction between ER and the age group in SCD (multivariate-adjusted $P = .048$). In addition, ER was associated with an increased risk of SCD in subjects under 50 in the multivariate analysis (HR 1.88; 95% CI 1.16–3.07; $P = .011$), whereas among subjects ≥50 years ER was not associated with an increased SCD risk. Figure 1 provides the survival plots according to age group for SCD adjusted for confounders.

Among subjects under 50, we detected a significant interaction between ER and sex in SCD after adjusting for age ($P = .024$), which did not remain significant in the multivariate analysis ($P = .092$). When women under 50 were analyzed separately, ER was associated with a high risk of SCD in both the age-adjusted (HR 5.34; 95% CI 1.88–15.19; $P = .002$) and multivariate-adjusted (HR 4.11; 95% CI 1.41–12.03; $P = .010$) analyses when compared to subjects without ER. Figure 2 provides an example ER pattern from a woman under 50 years old. In comparison, ER was not associated with SCD among men under 50. Neither men nor women under 50 with ER exhibited an increased risk for cardiac death or all-cause mortality.

Risk of SCD based on the ER pattern in subjects under 50

Table 3 summarizes the risks of SCD based on the ER pattern among subjects under 50 in the multivariate analyses. When assessed by ER localization, both inferior (HR 1.92; 95% CI 1.04–3.56; $P = .038$) and lateral (HR 2.08; 95% CI 1.10–3.95; $P = .024$) ER localizations were associated with SCD risk among subjects under 50. Furthermore, a slurred ER (HR 2.09; 95% CI 1.19–3.67; $P = .010$), ER with a horizontal or descending ST-segment (HR 3.12; 95% CI 1.56–6.26; $P = .001$), and ER with a low amplitude T-wave (HR 4.47; 95% CI 1.75–11.42; $P = .002$) were associated with SCD risk among subjects under 50 years old.

Discussion

We evaluated the prognosis associated with ER based on sex and age groups in a large representative population cohort with a long follow-up period. We found that ER was associated with an increased risk of SCD among adults aged 30–50 years, whereas no increased SCD risk was observed among subjects with ER aged ≥50 years. Furthermore, among subjects under 50, women with ER exhibited a high SCD risk, whereas ER was not associated with SCD among men.

In this study, ER prevalence reached 12.0% in the entire study population. In previous studies, the prevalence of ER ranged from 0.9% to 23.9%.[7,8,21] We defined ER following minor adjustments as recommended in a recent consensus paper. We measured the ER amplitude with respect to the true baseline determined as the T–P segment, compared to with respect to the QRS onset suggested by the consensus paper. This difference could have had an effect on the ER amplitude measurements, especially on tachycardic subjects. The ER definition used in the present study is similar albeit somewhat modified to that used in a previous Finnish middle-aged general population cohort study in which ER prevalence was 5.8%.[4,10,18] A possible explanation for the difference in the ER prevalence between these studies may lie in the improved ECG quality in the present study given the more modern recording device, as borderline cases would be determined ER positive in the present study and negative in the previous study. Concordant with previous studies, ER was more prevalent among men younger than 50, whereas no sex difference was identified among older subjects.[16] One possible explanation for this may lie in the association between ER and testosterone levels in men, which begin declining before the age of 50.[22]

Previously, few studies examined ER prognosis in different age groups. In a German cohort study, ER was associated with all-cause and cardiac mortality among subjects aged 35–54, while ER was not associated with an adverse prognosis in older age groups.[6] Similarly, in a Japanese cohort study, subjects aged <60 years with ER exhibited an increased risk for cardiac

death, while subjects with ER ≥60 years carried no such increased risk.[13] However, in young adults aged 18–30 in the United States, ER with an ascending ST-segment was not associated with adverse outcomes, and the prevalence of ER markedly decreased during the follow-up period.[14] Interestingly, the prevalence of ER with an ascending ST-segment appears to change in male and female subjects throughout puberty, while the prevalence of ER with a horizontal or descending ST-segment remains fairly constant among children, adolescents, and middle-aged subjects.[10,15,23]

To our knowledge, no previous studies examined the impact of age on SCD risk related to ER. In our study, subjects aged 30–50 years exhibited an increased risk of SCD, while ≥50-year-old subjects with ER showed no increase in SCD risk. Previous studies demonstrated that ER may predispose an individual to a fatal arrhythmia during ischemic or nonischemic events.[11,24] This vulnerability could manifest after a longer time period, perhaps explaining why ER was associated with SCD only among the younger subjects in our study. Furthermore, older subjects may have died due to other comorbidities before a critical event occurred. A plausible explanation could then be that ER in young adults, particularly with an ascending ST-segment, represents a benign ECG finding that normally disappears before middle age. This stands in contrast to a more constant and unchanging ER with a descending or horizontal ST-segment, which associates with a long-term vulnerability to more nefarious arrhythmias.[14–16] It may also be that the most malign ER phenotypes manifest at a younger age and, thus, the more benign ER phenotypes may be overrepresented among the very old. Moreover, as the risk of SCD increases with age, other factors may associate with SCD risk more strongly than ER in older individuals.

Previous studies have provided contradictory results on the impact of sex on ER prognosis. For example, a German study found that ER was associated with cardiac mortality in a subgroup of men, but not among women.[6] In contrast, a cohort study from the United States demonstrated an association between ER and SCD only among women.[9] However, in the same study population, automatically detected ER was associated with cardiovascular mortality only

among men.[25] We, however, observed an association between ER and the risk of SCD in women under 50, but not among men.

Various studies provide a large degree of heterogeneous results in their examinations of the risk associated with ER among general populations, with several studies finding no link between ER and an increased risk of adverse outcomes.[7,9,21] In the present study, we found that ER was not associated with SCD, cardiac mortality, or all-cause mortality across the entire study population. Possible explanations for these contradicting results across studies include the different study population characteristics, follow-up periods, and ER definitions applied. In addition, only a small minority of subjects with ER will eventually experience SCD, while the majority will enjoy benign prognoses. Therefore, future research should continue to refine or better define the specific patient characteristics and ER pattern features to more accurately identify that minority of individuals who will suffer an SCD. Better identifying such individuals will ultimately serve to improve their prognosis.

Limitations

Although the subjects underwent extensive health interviews and examinations at the beginning of the survey, the subjects' health status or the presence of ER in ECG were not reassessed during the follow-up period. Therefore, we had no information on whether participants' health status, comorbidities, or ER status changed during the follow-up period. Yet, ER has been shown to be relatively stable ECG finding among middle-aged subjects.[4] A further limitation to this study lies in the study population, which consisted of only Caucasian subjects. Thus, these results are not directly generalizable to other ethnicities.

Conclusions

In conclusion, among adults aged 30–50 years, ER associates with SCD. In particular, women under 50 years old with ER exhibited a higher risk of SCD, while ER was not associated with SCD among men <50 years old. In addition, we found that among subjects ≥50 years old, ER was not associated with an adverse prognosis at all. Future research should focus on identifying factors that account for the differences between age groups, and improving the risk stratification in younger patient populations with ER.

ER = early repolarization; QTc = QT corrected for heart rate using Bazett's formula. Continuous data are presented as means ± standard deviation, while categorical data are presented as the number of cases (% of study population). Statistical test for the difference between subjects with and without ER in all subjects, subjects aged <50 years, and subjects aged ≥50 years.

†Adjusted for age.

358

359 ER = early repolarization; SCD = sudden cardiac death. The hazard ratios (HRs) and 95%
360 confidence intervals (CIs) were calculated using the Cox proportional hazards model. Variables
361 included in the multivariate analyses were age as a continuous variable, sex, systolic blood pressure,
362 total serum cholesterol, coronary artery, diabetes, smoking, and ER. The effect modification was
363 tested by entering an interaction term for ER and the age group in the multivariate analysis.

Table 3

Risk of sudden cardiac death according to the ER pattern in subjects aged <50 years

	Age <50 years n = 3305
